Chapter 1

- **1.1.** A finite element is a small body or unit interconnected to other units to model a larger structure or system.
- **1.2.** Discretization means dividing the body (system) into an equivalent system of finite elements with associated nodes and elements.
- **1.3.** The modern development of the finite element method began in 1941 with the work of Hrennikoff in the field of structural engineering.
- **1.4.** The direct stiffness method was introduced in 1941 by Hrennikoff. However, it was not commonly known as the direct stiffness method until 1956.
- **1.5.** A matrix is a rectangular array of quantities arranged in rows and columns that is often used to aid in expressing and solving a system of algebraic equations.
- **1.6.** As computer developed it made possible to solve thousands of equations in a matter of minutes.
- **1.7.** The following are the general steps of the finite element method.
 - Step 1

Divide the body into an equivalent system of finite elements with associated nodes and choose the most appropriate element type.

Step 2

Choose a displacement function within each element.

Step 3

Relate the stresses to the strains through the stress/strain law—generally called the constitutive law.

Step 4

Derive the element stiffness matrix and equations. Use the direct equilibrium method, a work or energy method, or a method of weighted residuals to relate the nodal forces to nodal displacements.

Step 5

Assemble the element equations to obtain the global or total equations and introduce boundary conditions.

Step 6

Solve for the unknown degrees of freedom (or generalized displacements).

Step 7

Solve for the element strains and stresses.

Step 8

Interpret and analyze the results for use in the design/analysis process.

- **1.8.** The displacement method assumes displacements of the nodes as the unknowns of the problem. The problem is formulated such that a set of simultaneous equations is solved for nodal displacements.
- **1.9.** Four common types of elements are: simple line elements, simple two-dimensional elements, simple three-dimensional elements, and simple axisymmetric elements.
- 1.10 Three common methods used to derive the element stiffness matrix and equations are
 - (1) direct equilibrium method
 - (2) work or energy methods
 - (3) methods of weighted residuals
- **1.11.** The term 'degrees of freedom' refers to rotations and displacements that are associated with each node.

- **1.12.** Five typical areas where the finite element is applied are as follows.
 - (1) Structural/stress analysis
 - (2) Heat transfer analysis
 - (3) Fluid flow analysis
 - (4) Electric or magnetic potential distribution analysis
 - (5) Biomechanical engineering
- **1.13.** Five advantages of the finite element method are the ability to
 - (1) Model irregularly shaped bodies quite easily
 - (2) Handle general load conditions without difficulty
 - (3) Model bodies composed of several different materials because element equations are evaluated individually
 - (4) Handle unlimited numbers and kinds of boundary conditions
 - (5) Vary the size of the elements to make it possible to use small elements where necessary
